1 Introduction

This manual describes the programming language Cool: the Classroom Object-Oriented Language. Cool is a small language that can be implemented with reasonable effort in a one semester course. Still, Cool retains many of the features of modern programming languages including objects, static typing, and automatic memory management.

The original reference manual written by Alex Aiken for use at Berkeley and distributed with materials for instructors at other universities. This version was modified for use in the Spring 2006 and revised further in Winter 2010 for CIS 461/561 at University of Oregon. We are taking a somewhat different approach to the project, not using the library files and sample implementation. Some of the differences are noted in boxes like this one. A number of mostly cosmetic changes to syntax are not marked. Section 13 summarizing main differences between Cool and Java was added.

Cool programs are sets of classes. A class encapsulates the variables and procedures of a data type. Instances of a class are objects. In Cool, classes and types are identified; i.e., every class defines a type. Classes permit programmers to define new types and associated procedures (or methods) specific to those types. Inheritance allows new types to extend the behavior of existing types.

Cool is an expression language. Most Cool constructs are expressions, and every expression has a value and a type. Cool is type safe: procedures are guaranteed to be applied to data of the correct type. While static typing imposes a strong discipline on programming in Cool, it guarantees that no runtime type errors can arise in the execution of Cool programs.

This manual is divided into informal and formal components. For a short, informal overview, the first half (through Section 8) suffices. The formal description begins with Section 9.

2 Classes

All code in Cool is organized into classes. Each class definition must be contained in a single source file, but multiple classes may be defined in the same file. Class definitions have the form:

class <type> [ inherits <type> ] {
  <feature_list>
}
The notation \([ \ldots \]) denotes an optional construct. All class names are globally visible. Class names begin with an uppercase letter. Classes may not be redefined.

### 2.1 Features

The body of a class definition consists of a list of feature definitions. A feature is either an attribute or a method. An attribute of class \(A\) specifies a variable that is part of the state of objects of class \(A\). A method of class \(A\) is a procedure that may manipulate the variables and objects of class \(A\). Cool attributes have scope local to the class, and methods have global scope. Thus, the only way to provide access to object state in Cool is through methods.

Feature names must begin with a lowercase letter. No method name may be defined multiple times in a class, and no attribute name may be defined multiple times in a class, but a method and an attribute may have the same name.

A fragment from `list.cl` illustrates simple cases of both attributes and methods:

```cl
class Cons inherits List {
  xcar : Int;
  xcdr : List;

  isNil() : Bool { false };

  init(hd : Int, tl : List) : Cons {
    { 
      xcar := hd;
      xcdr := tl;
      self;
    }
  }
}
...
}
```

In this example, the class `Cons` has two attributes `xcar` and `xcdr` and two methods `isNil` and `init`. Note that the types of attributes, as well as

---

1. An attribute is like a “field” or a “data member” in other object-oriented languages.
the types of formal parameters and return types of methods, are explicitly declared by the programmer.

Given object \( c \) of class \( \text{Cons} \) and object \( l \) of class \( \text{List} \), we can set the \( \text{xcar} \) and \( \text{xcdr} \) fields by using the method \( \text{init} \):

\[
c.\text{init}(1,l)
\]

This notation is \textit{object-oriented dispatch}. There may be many definitions of \( \text{init} \) methods in many different classes. The dispatch looks up the class of the object \( c \) to decide which \( \text{init} \) method to invoke. Because the class of \( c \) is \( \text{Cons} \), the \( \text{init} \) method in the \( \text{Cons} \) class is invoked. Within the invocation, the variables \( \text{xcar} \) and \( \text{xcdr} \) refer to \( c \)'s attributes. The special variable \textit{self} refers to the object on which the method was dispatched, which, in the example, is \( c \) itself.

There is a special form \textit{new C} that generates a fresh object of class \( C \). An object can be thought of as a record that has a slot for each of the attributes of the class as well as pointers to the methods of the class. A typical dispatch for the \( \text{init} \) method is:

\[
(\text{new Cons}).\text{init}(1,\text{new Nil})
\]

This example creates a new cons cell and initializes the “car” of the cons cell to be \( 1 \) and the “cdr” to be \textit{new Nil}. There is no mechanism in Cool for programmers to deallocate objects. Cool has \textit{automatic memory management}; objects that cannot be used by the program are deallocated by a runtime garbage collector.

Attributes are discussed further in Section 4 and methods are discussed further in Section 5.

### 2.2 Inheritance

If a class definition has the form

```plaintext
class C inherits P { ... };
```

then class \( C \) inherits the features of \( P \). In this case \( P \) is the \textit{parent} class of \( C \) and \( C \) is a \textit{child} class of \( P \).

The semantics of \( C \) \textit{inherits} \( P \) is that \( C \) has all of the features defined in \( P \) in addition to its own features. In the case that a parent and child both define the same method name, then the definition given in the child class

\footnote{In this example, \textit{Nil} is assumed to be a subtype of \textit{List}.}
takes precedence. It is illegal to redefine attribute names. Furthermore, for
type safety, it is necessary to place some restrictions on how methods may
be redefined (see Section 3).

There is a distinguished class Object. If a class definition does not
specify a parent class, then the class inherits from Object by default. A class
may inherit only from a single class; this is aptly called “single inheritance.”

The parent-child relation on classes defines a graph. This graph may not
contain cycles. For example, if C inherits from P, then P must not inherit
from C. Furthermore, if C inherits from P, then P must have a class definition
somewhere in the program. Because Cool has single inheritance, it follows
that if both of these restrictions are satisfied, then the inheritance graph
forms a tree with Object as the root.

In addition to Object, Cool has four other basic classes: Int, String,
Bool, and IO. The basic classes are discussed in Section 7.

3 Types

In Cool, every class name is also a type. In addition, there is a type
SELF_TYPE that can be used in special circumstances.

A type declaration has the form x:C, where x is a variable and C is a type.
Every variable must have a type declaration at the point it is introduced,
whether that is in a let, case, or as the formal parameter of a method.
The types of all attributes must also be declared.

The basic type rule in Cool is that if a method or variable expects a
value of type P, then any value of type C may be used instead, provided that
P is an ancestor of C in the class hierarchy. In other words, if C inherits from
P, either directly or indirectly, then a C can be used wherever a P would
suffice.

When an object of class C may be used in place of an object of class P,
we say that C conforms to P or that C ≤ P (think: C is lower down in the
inheritance tree). As discussed above, conformance is defined in terms of
the inheritance graph.

Definition 3.1 (Conformance) Let A, C, and P be types.

- A ≤ A for all types A

\(^3\)Some object-oriented languages allow a class to inherit from multiple classes, which
is equally aptly called “multiple inheritance.”
• if C inherits from P, then C ≤ P
• if A ≤ C and C ≤ P then A ≤ P

Because Object is the root of the class hierarchy, it follows that A ≤ Object for all types A.

3.1 SELF_TYPE

The self type is optional. At the very least, get everything else working before worrying about this. Feel free to just skip it.

The type SELF_TYPE is used to refer to the type of the self variable. This is useful in classes that will be inherited by other classes, because it allows the programmer to avoid specifying a fixed final type at the time the class is written. For example, the program

class Silly {
    copy() : SELF_TYPE { self; }
};
class Sally inherits Silly { };
class Main {
    x : Sally := (new Sally).copy();
    main() : Sally { x; }
};

Because SELF_TYPE is used in the definition of the copy method, we know that the result of copy is the same as the type of the self parameter. Thus, it follows that (new Sally).copy() has type Sally, which conforms to the declaration of attribute x.

Note that the meaning of SELF_TYPE is not fixed, but depends on the class in which it is used. In general, SELF_TYPE may refer to the class C in which it appears, or any class that conforms to C. When it is useful to make explicit what SELF_TYPE may refer to, we use the name of the class C in which SELF_TYPE appears as an index SELF_TYPE_C. This subscript notation is not part of Cool syntax—it is used merely to make clear in what class a particular occurrence of SELF_TYPE appears.

From Definition 3.1 it follows that SELF_TYPE_X ≤ SELF_TYPE_X. There is also a special conformance rule for SELF_TYPE:

SELF_TYPE_C ≤ P if C ≤ P
Finally, `SELF_TYPE` may be used in the following places: new `SELF_TYPE`, as the return type of a method, as the declared type of a `let` variable, or as the declared type of an attribute. No other uses of `SELF_TYPE` are permitted.

### 3.2 Type Checking

The Cool type system guarantees at compile time that execution of a program cannot result in runtime type errors. Using the type declarations for identifiers supplied by the programmer, the type checker infers a type for every expression in the program.

It is important to distinguish between the type assigned by the type checker to an expression at compile time, which we shall call the *static* type of the expression, and the type(s) to which the expression may evaluate during execution, which we shall call the *dynamic* types.

The distinction between static and dynamic types is needed because the type checker cannot, at compile time, have perfect information about what values will be computed at runtime. Thus, in general, the static and dynamic types may be different. What we require, however, is that the type checker’s static types be *sound* with respect to the dynamic types.

**Definition 3.2** For any expression \( e \), let \( D_e \) be a dynamic type of \( e \) and let \( S_e \) be the static type inferred by the type checker. Then the type checker is *sound* if for all expressions \( e \) it is the case that \( D_e \leq S_e \).

Put another way, we require that the type checker err on the side of overestimating the type of an expression in those cases where perfect accuracy is not possible. Such a type checker will never accept a program that contains type errors. However, the price paid is that the type checker will reject some programs that would actually execute without runtime errors.

### 4 Attributes

An attribute definition has the form

\[
\langle \text{id} \rangle : \langle \text{type} \rangle \ [\ := \langle \text{expr} \rangle \ ];
\]

The expression is optional initialization that is executed when a new object is created. The static type of the expression must conform to the declared type of the attribute. If no initialization is supplied, then the default initialization is used (see below).
When a new object of a class is created, all of the inherited and local attributes must be initialized. Inherited attributes are initialized first in inheritance order beginning with the attributes of the greatest ancestor class. Within a given class, attributes are initialized in the order they appear in the source text.

Attributes are local to the class in which they are defined or inherited. Inherited attributes cannot be redefined.

4.1 Void

All variables in Cool are initialized to contain values of the appropriate type. The special value void is a member of all types and is used as the default initialization for variables where no initialization is supplied by the user. (void is used where one would use NULL in C or null in Java; Cool does not have anything equivalent to C’s or Java’s void type.) Note that there is no name for void in Cool; the only way to create a void value is to declare a variable of some class other than Int, String, or Bool and allow the default initialization to occur, or to store the result of a while loop.

There is a special form isvoid expr that tests whether a value is void (see Section 6.11). In addition, void values may be tested for equality. A void value may be passed as an argument, assigned to a variable, or otherwise used in any context where any value is legitimate, except that a dispatch to or case on void generates a runtime error.

Variables of the basic classes Int, Bool, and String are initialized specially; see Section 7.

5 Methods

A method definition has the form

<id>(<id> : <type>,...,<id> : <type>): <type> { <expr> };

There may be zero or more formal parameters. The identifiers used in the formal parameter list must be distinct. The type of the method body must conform to the declared return type. When a method is invoked, the formal parameters are bound to the actual arguments and the expression is evaluated; the resulting value is the meaning of the method invocation. A formal parameter hides any definition of an attribute of the same name.

To ensure type safety, there are restrictions on the redefinition of inherited methods. The rule is simple: If a class C inherits a method f from an
ancestor class P, then C may override the inherited definition of f provided the number of arguments, the types of the formal parameters, and the return type are exactly the same in both definitions.

To see why some restriction is necessary on the redefinition of inherited methods, consider the following example:

class P {
    f(): Int { 1 };  
};

class C inherits P {
    f(): String { "1" };  
};

Let p be an object with dynamic type P. Then

p.f() + 1

is a well-formed expression with value 2. However, we cannot substitute a value of type C for p, as it would result in adding a string to a number. Thus, if methods can be redefined arbitrarily, then subclasses may not simply extend the behavior of their parents, and much of the usefulness of inheritance, as well as type safety, is lost.

6 Expressions

Expressions are the largest syntactic category in Cool.

6.1 Constants

The simplest expressions are constants. The boolean constants are true and false. Integer constants are unsigned strings of digits such as 0, 123, and 007. String constants are sequences of characters enclosed in double quotes, such as "This is a string." String constants may be at most 1024 characters long. There are other restrictions on strings; see Section 9.

The constants belong to the basic classes Bool, Int, and String. The value of a constant is an object of the appropriate basic class.

6.2 Identifiers

The names of local variables, formal parameters of methods, self, and class attributes are all expressions. The identifier self may be referenced, but it
is an error to assign to `self` or to bind `self` in a `let`, a `case`, or as a formal parameter. It is also illegal to have attributes named `self`.

Local variables and formal parameters have lexical scope. Attributes are visible throughout a class in which they are declared or inherited, although they may be hidden by local declarations within expressions. The binding of an identifier reference is the innermost scope that contains a declaration for that identifier, or to the attribute of the same name if there is no other declaration. The exception to this rule is the identifier `self`, which is implicitly bound in every class.

### 6.3 Assignment

An assignment has the form

```plaintext
{id} := {expr}
```

The static type of the expression must conform to the declared type of the identifier. The value is the value of the expression. The static type of an assignment is the static type of `{expr}`.

### 6.4 Dispatch

There are three forms of dispatch (i.e. method call) in Cool. The three forms differ only in how the called method is selected. The most commonly used form of dispatch is

```plaintext
{expr}.{id}(<expr>,...,<expr>)
```

Consider the dispatch `e_0.f(e_1, ..., e_n)`. To evaluate this expression, the arguments are evaluated in left-to-right order, from `e_1` to `e_n`. Next, `e_0` is evaluated and its class `C` noted (if `e_0` is `void` a runtime error is generated). Finally, the method `f` in class `C` is invoked, with the value of `e_0` bound to `self` in the body of `f` and the actual arguments bound to the formals as usual. The value of the expression is the value returned by the method invocation.

Type checking a dispatch involves several steps. Assume `e_0` has static type `A`. (Recall that this type is not necessarily the same as the type `C` above. `A` is the type inferred by the type checker; `C` is the class of the object computed at runtime, which is potentially any subclass of `A`.) Class `A` must have a method `f`, the dispatch and the definition of `f` must have the same number of arguments, and the static type of the `i`th actual parameter must conform to the declared type of the `i`th formal parameter.
If \( f \) has return type \( B \) and \( B \) is a class name, then the static type of the dispatch is \( B \). Otherwise, if \( f \) has return type \( \text{SELF\_TYPE} \), then the static type of the dispatch is \( A \). To see why this is sound, note that the \texttt{self} parameter of the method \( f \) conforms to type \( A \). Therefore, because \( f \) returns \( \text{SELF\_TYPE} \), we can infer that the result must also conform to \( A \). Inferring accurate static types for dispatch expressions is what justifies including \( \text{SELF\_TYPE} \) in the Cool type system.

The other forms of dispatch are:

\[
\langle\text{id}\rangle(<\text{expr}>,...,<\text{expr}>)
\]
\[
<\text{expr}>\langle\text{type}\rangle..\text{id}(<\text{expr}>,...,<\text{expr}>)
\]

The first form is shorthand for \( \text{self.}\langle\text{id}\rangle(<\text{expr}>,...,<\text{expr}>) \).

The second form provides a way of accessing methods of parent classes that have been hidden by redefinitions in child classes. Instead of using the class of the leftmost expression to determine the method, the method of the class explicitly specified is used. For example, \( \text{e}\langle\text{B}\rangle..\text{f}() \) invokes the method \( \text{f} \) in class \( \text{B} \) on the object that is the value of \( \text{e} \). For this form of dispatch, the static type to the left of “\( @ \)” must conform to the type specified to the right of “\( @ \)”.

## 6.5 Conditionals

A conditional has the form

\[
\text{if } <\text{expr}> \text{ then } <\text{expr}> \text{ else } <\text{expr}> \text{ fi}
\]

The semantics of conditionals is standard. The predicate is evaluated first. If the predicate is \texttt{true}, then the \texttt{then} branch is evaluated. If the predicate is \texttt{false}, then the \texttt{else} branch is evaluated. The value of the conditional is the value of the evaluated branch.

The predicate must have static type \( \text{Bool} \). The branches may have any static types. To specify the static type of the conditional, we define an operation \( \sqcup \) (pronounced “join”) on types as follows. Let \( A,B,D \) be any types other than \( \text{SELF\_TYPE} \). The least type of a set of types means the least element with respect to the conformance relation \( \leq \).

\[
A \sqcup B = \text{the least type } C \text{ such that } A \leq C \text{ and } B \leq C
\]
\[
A \sqcup A = A \quad \text{(idempotent)}
\]
\[
A \sqcup B = B \sqcup A \quad \text{(commutative)}
\]
\[
\text{SELF\_TYPE}_D \sqcup A = D \sqcup A
\]

13
Let T and F be the static types of the branches of the conditional. Then the static type of the conditional is $T \sqcup F$. (think: Walk towards Object from each of T and F until the paths meet.)

### 6.6 Loops

A loop has the form

```
while <expr> do <expr> od
```

The predicate is evaluated before each iteration of the loop. If the predicate is `false`, the loop terminates and `void` is returned. If the predicate is `true`, the body of the loop is evaluated and the process repeats.

The predicate must have static type `Bool`. The body may have any static type. The static type of a loop expression is `Object`.

### 6.7 Blocks

A block has the form

```
{ <expr>; ... <expr>; }
```

The expressions are evaluated in left-to-right order. Every block has at least one expression; the value of a block is the value of the last expression. The expressions of a block may have any static types. The static type of a block is the static type of the last expression.

An occasional source of confusion in Cool is the use of semi-colons (";"). Semi-colons are used as terminators in lists of expressions (e.g., the block syntax above) and not as expression separators. Semi-colons also terminate other Cool constructs, see Section 10 for details.

### 6.8 Let

A let expression has the form

```
let <id1> : <type1> [ := <expr1> ],
...
<idn> : <typen> [ := <exprn> ] in <expr>
```

The optional expressions are `initialization`; the other expression is the `body`. A `let` is evaluated as follows. First `<expr1>` is evaluated and the result bound to `<id1>`. Then `<expr2>` is evaluated and the result bound to `<id2>`, and so on, until all of the variables in the `let` are initialized. (If the
initialization of <idk> is omitted, the default initialization of type <typek> is used.) Next the body of the let is evaluated. The value of the let is the value of the body.

The let identifiers <id1>,...,<idn> are visible in the body of the let. Furthermore, identifiers <id1>,...,<idk> are visible in the initialization of <idm> for any m > k.

If an identifier is defined multiple times in a let, later bindings hide earlier ones. Identifiers introduced by let also hide any definitions for the same names in containing scopes. Every let expression must introduce at least one identifier.

The type of an initialization expression must conform to the declared type of the identifier. The type of let is the type of the body.

The <expr> of a let extends as far (encompasses as many tokens) as the grammar allows.

### 6.9 Case

A case expression has the form

```plaintext
case <expr0> of
  <id1> : <type1> => <expr1>;
  . . .
  <idn> : <typename> => <exprn>;
esac
```

Case expressions provide runtime type tests on objects. First, <expr0> is evaluated and its dynamic type C noted (if <expr0> evaluates to void a run-time error is produced). Next, from among the branches the branch with the least type <typek> such that C ≤ <typek> is selected. The identifier <idk> is bound to the value of <expr0> and the expression <exprk> is evaluated. The result of the case is the value of <exprk>. If no branch can be selected for evaluation, a run-time error is generated. Every case expression must have at least one branch.

For each branch, let T_i be the static type of <expri>. The static type of a case expression is \( \bigcup_{1 \leq i \leq n} T_i \). The identifier id introduced by a branch of a case hides any variable or attribute definition for id visible in the containing scope.

The case expression has no special construct for a “default” or “otherwise” branch. The same affect is achieved by including a branch

```
x : Object => ...
```
because every type is $\leq$ to Object.

The case expression provides programmers a way to insert explicit runtime type checks in situations where static types inferred by the type checker are too conservative. A typical situation is that a programmer writes an expression $e$ and type checking infers that $e$ has static type $P$. However, the programmer may know that, in fact, the dynamic type of $e$ is always $C$ for some $C \leq P$. This information can be captured using a case expression:

```
case e of x : C => ... 
```

In the branch the variable $x$ is bound to the value of $e$ but has the more specific static type $C$.

### 6.10 New

A new expression has the form

```
new <type>
```

The value is a fresh object of the appropriate class. If the type is SELF_TYPE, then the value is a fresh object of the class of self in the current scope. The static type is <type>.

### 6.11 Isvoid

The expression

```
isvoid expr
```

evaluates to true if expr is void and evaluates to false if expr is not void.

### 6.12 Arithmetic and Comparison Operations

Cool has four binary arithmetic operations: $+$, $-$, $\ast$, $/$. The syntax is

```
expr1 <op> expr2
```

To evaluate such an expression first $expr1$ is evaluated and then $expr2$. The result of the operation is the result of the expression.

The static types of the two sub-expressions must be Int. The static type of the expression is Int. Cool has only integer division.

Cool has three comparison operations: $<$, $\leq$, $=$. For $<$ and $\leq$ the rules are exactly the same as for the binary arithmetic operations, except that the result is a Bool. The comparison $=$ is a special case. If either $<expr1>$ or
<expr2> has static type `Int`, `Bool`, or `String`, then the other must have the same static type. Any other types, including `SELF_TYPE`, may be freely compared. On non-basic objects, equality simply checks for pointer equality (i.e., whether the memory addresses of the objects are the same). Equality is defined for `void`.

In principle, there is nothing wrong with permitting equality tests between, for example, `Bool` and `Int`. However, such a test must always be false and almost certainly indicates some sort of programming error. The Cool type checking rules catch such errors at compile-time instead of waiting until runtime.

Finally, there is one arithmetic and one logical unary operator. The expression `~<expr>` is the integer complement of `<expr>`. The expression `<expr>` must have static type `Int` and the entire expression has static type `Int`. The expression `not <expr>` is the boolean complement of `<expr>`. The expression `<expr>` must have static type `Bool` and the entire expression has static type `Bool`.

7 Basic Classes

7.1 Object

The `Object` class is the root of the inheritance graph. Methods with the following declarations are defined:

```
abort() : Object
type_name() : String
copy() : SELF_TYPE
```

The method `abort` halts program execution with an error message. The method `type_name` returns a string with the name of the class of the object. The method `copy` produces a shallow copy of the object.

7.2 IO

The `IO` class provides the following methods for performing simple input and output operations:

```
out_string(x : String) : SELF_TYPE
out_int(x : Int) : SELF_TYPE
```

---

4A shallow copy of a copies a itself, but does not recursively copy objects that a points to.
in_string() : String
in_int() : Int

Obviously, if you don’t implement SELF_TYPE, the signatures of
the IO library will have to change. Do something reasonable, and
document it so that we’ll know what we need to do in test cases.

The methods **out_string** and **out_int** print their argument and return
their **self** parameter. The method **in_string** reads a string from the stan-
dard input, up to but not including a newline character. The method **in_int**
reads a single integer, which may be preceded by whitespace. Any characters
following the integer, up to and including the next newline, are discarded
by **in_int**.

A class can make use of the methods in the **IO** class by inheriting from
**IO**. It is an error to redefine the **IO** class.

### 7.3 Int

The **Int** class provides integers. There are no methods special to **Int**. The
default initialization for variables of type **Int** is 0 (not void). It is an error
to inherit from or redefine **Int**.

### 7.4 String

The **String** class provides strings. The following methods are defined:

- **length()** : Int
- **concat(s : String) : String**
- **substr(i : Int, l : Int) : String**

The method **length** returns the length of the **self** parameter. The method
**concat** returns the string formed by concatenating **s after self**. The
method **substr** returns the substring of its **self** parameter beginning at
position **i** with length **l**; string positions are numbered beginning at 0. A
runtime error is generated if the specified substring is out of range.

The default initialization for variables of type **String** is "" (not void). It
is an error to inherit from or redefine **String**.

### 7.5 Bool

The **Bool** class provides **true** and **false**. The default initialization for
variables of type **Bool** is **false** (not void). It is an error to inherit from or
redefine **Bool**.
8 Main Class

Every program must have a class Main. Furthermore, the Main class must have a method main that takes no formal parameters. The main method must be defined in class Main (not inherited from another class). A program is executed by evaluating (new Main).main().

The remaining sections of this manual provide a more formal definition of Cool. There are four sections covering lexical structure (Section 9), grammar (Section 10), type rules (Section 11), and operational semantics (Section 12).

9 Lexical Structure

The lexical units of Cool are integers, type identifiers, object identifiers, special notation, strings, keywords, and white space.

9.1 Integers, Identifiers, and Special Notation

Integers are non-empty strings of digits 0-9. Identifiers are strings (other than keywords) consisting of letters, digits, and the underscore character. Type identifiers begin with a capital letter; object identifiers begin with a lower case letter. There are two other identifiers, self and SELF_TYPE that are treated specially by Cool but are not treated as keywords. The special syntactic symbols (e.g., parentheses, assignment operator, etc.) are given in Figure 1.

9.2 Strings

Strings are enclosed in double quotes "...". Within a string, a sequence \c denotes the character 'c', with the exception of the following:

\b backspace
\t tab
\n newline
\f formfeed

A non-escaped newline character may not appear in a string:

"This \
is OK"
"This is not OK"
A string may not contain the character control-D, which is conventionally used in Unix systems to signal end-of-file. Any other character may be included in a string. Strings cannot cross file boundaries.

9.3 Comments

There are two forms of comments in Cool. Any characters between two dashes “--” and the next newline (or EOF, if there is no next newline) are treated as comments. Comments may also be written by enclosing text in (∗ . . . ∗). Comments may not be nested or cross file boundaries.

The original Cool manual allowed nested comments. This is an optional feature. If you allow comments of the form (∗ . . . ∗) to nest, you must consider carefully how this feature interacts with “--” comments: What do you do with

-- (∗
Is this in a comment?
(∗ -- ∗)
How about this?
∗) -- legal?

My suggestion would be that the first of question above is not within a comment (the comment-begin sequence (∗ has no effect within a line-ending comment) and neither is the second (the line-ending comment has no effect between (∗ and ∗). Your scanner should see that the last ∗) appears outside a comment and give an appropriate error message.

9.4 Keywords

The keywords of cool are: class, else, false, fi, if, in, inherits, isvoid, let, do, od, then, while, case, esac, new, of, not, true. Keywords are case-sensitive (i.e., while is a keyword, but “While” could be the name of a class and “wHiLe” could be the name of an attribute or local variable).

Keywords were case-insensitive in the original definition of Cool. It is simple but tedious to recognize case-insensitive keywords in your scanner, and it seems pointless. Also, the original definition of Cool used loop...pool in place of do...od.
9.5 White Space

White space consists of any sequence of the characters: blank (ascii 32), \n (newline, ascii 10), \f (form feed, ascii 12), \r (carriage return, ascii 13), \t (tab, ascii 9), \v (vertical tab, ascii 11).

10 Cool Syntax

Figure provides a specification of Cool syntax. The specification is not in pure Backus-Naur Form (BNF); for convenience, we also use some regular expression notation. Specifically, $A^*$ means zero or more $A$'s in succession; $A^+$ means one or more $A$'s. The special notation $A;^*$ means zero or more $A$'s terminated by semicolons. The special notation $A;^*$ means zero or more $A$'s separated by commas. Separators differ from terminators in that the terminator always appears at the end of the list; a separator is never included at the end of a list. In Cool, semicolons are always terminators and commas are always separators. Items in square brackets [...] are optional. Double braces [...] are not part of Cool; they are used in the grammar as a meta-symbol to show association of grammar symbols (e.g. $a[bc]^+$ means $a$ followed by one or more $bc$ pairs).

10.1 Precedence

The precedence of infix binary and prefix unary operations, from highest to lowest, is given by the following table:

```plaintext
. @ -
isvoid *
/ + -
<= < = not :
```

All binary operations are left-associative, with the exception of assignment, which is right-associative, and the three comparison operations, which do not associate.
program ::= class;

class ::= class TYPE [inherits TYPE] { feature,* }

feature ::= ID(formal,*):TYPE { expr }
| ID : TYPE [ := expr ]

formal ::= ID : TYPE

expr ::= ID := expr
| expr[@TYPE].ID(expr,* )

Figure 1: Cool syntax.
11 Type Rules

This section formally defines the type rules of Cool. The type rules define the type of every Cool expression in a given context. The context is the *type environment*, which describes the type of every unbound identifier appearing in an expression. The type environment is described in Section 11.1. Section 11.2 gives the type rules.

11.1 Type Environments

To a first approximation, type checking in Cool can be thought of as a bottom-up algorithm: the type of an expression $e$ is computed from the (previously computed) types of $e$'s subexpressions. For example, an integer 1 has type Int; there are no subexpressions in this case. As another example, if $e_n$ has type $X$, then the expression \{ $e_1; \ldots; e_n; \}$ has type $X$.

A complication arises in the case of an expression $v$, where $v$ is an object identifier. It is not possible to say what the type of $v$ is in a strictly bottom-up algorithm; we need to know the type declared for $v$ in the larger expression. Such a declaration must exist for every object identifier in valid Cool programs.

To capture information about the types of identifiers, we use a *type environment*. The environment consists of three parts: a method environment $M$, an object environment $O$, and the name of the current class in which the expression appears. The method environment and object environment are both functions (also called *mappings*). The object environment is a function of the form

$$O(v) = T$$

which assigns the type $T$ to object identifier $v$. The method environment is more complex; it is a function of the form

$$M(C, f) = (T_1, \ldots, T_{n-1}, T_n)$$

where $C$ is a class name (a type), $f$ is a method name, and $t_1, \ldots, t_n$ are types. The tuple of types is the *signature* of the method. The interpretation of signatures is that in class $C$ the method $f$ has formal parameters of types $(t_1, \ldots, t_{n-1})$—in that order—and a return type $t_n$.

Two mappings are required instead of one because object names and method names do not clash—i.e., there may be a method and an object identifier of the same name.

The third component of the type environment is the name of the current class, which is needed for type rules involving SELF_TYPE.
Every expression $e$ is type checked in a type environment; the subexpressions of $e$ may be type checked in the same environment or, if $e$ introduces a new object identifier, in a modified environment. For example, consider the expression

\begin{verbatim}
let c : Int := 33 in
...
\end{verbatim}

The `let` expression introduces a new variable $c$ with type `Int`. Let $O$ be the object component of the type environment for the `let`. Then the body of the `let` is type checked in the object type environment

$$O[\text{Int}/c]$$

where the notation $O[T/c]$ is defined as follows:

$$O[T/c](c) = T$$
$$O[T/c](d) = O(d) \text{ if } d \neq c$$

### 11.2 Type Checking Rules

The general form a type checking rule is:

\[
\frac{}{O, M, C \vdash e : T} \quad \text{[NAME]}
\]

The rule should be read: In the type environment for objects $O$, methods $M$, and containing class $C$, the expression $e$ has type $T$. The dots above the horizontal bar stand for other statements about the types of sub-expressions of $e$. These other statements are hypotheses of the rule; if the hypotheses are satisfied, then the statement below the bar is true. In the conclusion, the “turnstile” ("\(\vdash\)”) separates context $(O, M, C)$ from statement $(e : T)$.

The rule for object identifiers is simply that if the environment assigns an identifier $Id$ type $T$, then $Id$ has type $T$.

\[
\frac{O(\text{Id}) = T}{O, M, C \vdash \text{Id} : T} \quad \text{[Var]}
\]

The rule for assignment to a variable is more complex:

\[
\frac{O(\text{Id}) = T}{O, M, C \vdash \text{Id} \leftarrow e_1 : T'} \quad \text{[ASSIGN]}
\]

\[
\frac{O(\text{Id}) = T}{O, M, C \vdash \text{Id} \leftarrow e_1 : T'}
\]

24
Note that this type rule—as well as others—use the conformance relation \( \leq \) (see Section 2.2). The rule says that the assigned expression \( e_1 \) must have a type \( T' \) that conforms to the type \( T \) of the identifier \( Id \) in the type environment. The type of the whole expression is \( T'' \).

The type rules for constants are all easy:

\[
O, M, C \vdash true : Bool \\
O, M, C \vdash false : Bool \\
O, M, C \vdash i : Int \\
O, M, C \vdash s : String
\]

There are two cases for \( \text{new} \), one for \( \text{new SELF_TYPE} \) and one for any other form:

\[
T' = \begin{cases}
    \text{SELF_TYPE}_C & \text{if } T = \text{SELF_TYPE} \\
    T & \text{otherwise}
\end{cases}
\]

\[
O, M, C \vdash \text{new } T : T'
\]

Dispatch expressions are the most complex to type check.

\[
O, M, C \vdash e_0 : T_0 \\
O, M, C \vdash e_1 : T_1 \\
\vdots \\
O, M, C \vdash e_n : T_n \\
T_0' = \begin{cases}
    C & \text{if } T_0 = \text{SELF_TYPE}_C \\
    T_0 & \text{otherwise}
\end{cases} \\
M(T_0', f) = (T_1', \ldots, T_n', T_{n+1}') \\
T_i \leq T_i' & 1 \leq i \leq n \\
T_{n+1} = \begin{cases}
    T_0 & \text{if } T_{n+1}' = \text{SELF_TYPE} \\
    T_{n+1}' & \text{otherwise}
\end{cases}
\]

\[
O, M, C \vdash e_0.f(e_1, \ldots, e_n) : T_{n+1}
\]
$O, M, C \vdash e_0 : T_0$

$O, M, C \vdash e_1 : T_1$

$\vdots$

$O, M, C \vdash e_n : T_n$

$T_0 \leq T$

$M(T, f) = (T_1', \ldots, T_n', T_{n+1}')$

$T_i \leq T_i' \quad 1 \leq i \leq n$

$T_{n+1} = \begin{cases} 
T_0 & \text{if } T_{n+1}' = \text{SELF\_TYPE} \\
T_{n+1}' & \text{otherwise} 
\end{cases}$

$O, M, C \vdash e_0 @ T.f(e_1, \ldots, e_n) : T_{n+1}$  \hspace{1cm} \text{[StaticDispatch]}

To type check a dispatch, each of the subexpressions must first be type checked. The type $T_0$ of $e_0$ determines which declaration of the method $f$ is used. The argument types of the dispatch must conform to the declared argument types. Note that the type of the result of the dispatch is either the declared return type or $T_0$ in the case that the declared return type is \text{SELF\_TYPE}. The only difference in type checking a static dispatch is that the class $T$ of the method $f$ is given in the dispatch, and the type $T_0$ must conform to $T$.

The type checking rules for \textit{if} and \{\} expressions are straightforward. See Section 6.5 for the definition of the \$\sqcup\$ operation.

$O, M, C \vdash e_1 : \text{Bool}$

$O, M, C \vdash e_2 : T_2$

$O, M, C \vdash e_3 : T_3$

$O, M, C \vdash \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \text{ fi} : T_2 \sqcup T_3$  \hspace{1cm} \text{[If]}

$O, M, C \vdash e_1 : T_1$

$O, M, C \vdash e_2 : T_2$

$\vdots$

$O, M, C \vdash e_n : T_n$

$O, M, C \vdash \{ e_1; e_2; \ldots; e_n; \} : T_n$  \hspace{1cm} \text{[Sequence]}

The \textit{let} rule has some interesting aspects.

$T_0' = \begin{cases} 
\text{SELF\_TYPE} & \text{if } T_0 = \text{SELF\_TYPE} \\
T_0' & \text{otherwise} 
\end{cases}$

$O, M, C \vdash e_1 : T_1$

$T_1 \leq T_0'$

$O[T_0' / x], M, C \vdash e_2 : T_2$

$O, M, C \vdash \text{let } x : T_0 \leftarrow e_1 \text{ in } e_2 : T_2$  \hspace{1cm} \text{[Let-Init]}

26
First, the initialization $e_1$ is type checked in an environment without a new definition for $x$. Thus, the variable $x$ cannot be used in $e_1$ unless it already has a definition in an outer scope. Second, the body $e_2$ is type checked in the environment $O$ extended with the typing $x : T'_0$. Third, note that the type of $x$ may be $\text{SELF\_TYPE}$.

\[
T'_0 = \begin{cases} 
\text{SELF\_TYPE} & \text{if } T_0 = \text{SELF\_TYPE} \\
T_0 & \text{otherwise} 
\end{cases}
\]

\[
O[T'_0/x], M, C \vdash e_1 : T_1
\]

\[
O, M, C \vdash \text{let } x : T_0 \text{ in } e_1 : T_1
\]  

[Let-No-Init]

The rule for let with no initialization simply omits the conformance requirement. We give type rules only for a let with a single variable. Typing a multiple let

\[
\text{let } x_1 : T_1 [\leftarrow e_1], x_2 : T_2 [\leftarrow e_2], \ldots, x_n : T_n [\leftarrow e_n] \text{ in } e
\]

is defined to be the same as typing

\[
\text{let } x_1 : T_1 [\leftarrow e_1] \text{ in } (\text{let } x_2 : T_2 [\leftarrow e_2], \ldots, x_n : T_n [\leftarrow e_n] \text{ in } e)
\]

\[
O, M, C \vdash e_0 : T_0
\]

\[
O[T_1/x_1], M, C \vdash e_1 : T'_1
\]

\[
\vdots
\]

\[
O[T_n/x_n], M, C \vdash e_n : T'_n
\]

\[
O, M, C \vdash \text{case } e_0 \text{ of } x_1 : T_1 \Rightarrow e_1; \ldots; x_n : T_n \Rightarrow e_n; \text{ esac} : \bigsqcup_{1 \leq i \leq n} T'_i
\]  

[Case]

Each branch of a case is type checked in an environment where variable $x_i$ has type $T_i$. The type of the entire case is the join of the types of its branches. The variables declared on each branch of a case must all have distinct types.

\[
O, M, C \vdash e_1 : \text{Bool}
\]

\[
O, M, C \vdash e_2 : T_2
\]

\[
O, M, C \vdash \text{while } e_1 \text{ loop } e_2 \text{ pool : Object}
\]  

[Loop]

The predicate of a loop must have type $\text{Bool}$; the type of the entire loop is always $\text{Object}$. An isvoid test has type $\text{Bool}$:

\[
O, M, C \vdash e_1 : T_1
\]

\[
O, M, C \vdash \text{isvoid } e_1 : \text{Bool}
\]  

[Isvoid]
With the exception of the rule for equality, the type checking rules for
the primitive logical, comparison, and arithmetic operations are easy.

\[
O, M, C \vdash e_1 : \text{Bool} \\
\overline{O, M, C \vdash \neg e_1 : \text{Bool}} \quad \text{[Not]}
\]

\[
O, M, C \vdash e_1 : \text{Int} \\
O, M, C \vdash e_2 : \text{Int} \\
op \in \{<, \leq\} \\
\overline{O, M, C \vdash e_1 \, \text{op} \, e_2 : \text{Bool}} \quad \text{[Compare]}
\]

\[
O, M, C \vdash e_1 : \text{Int} \\
\overline{O, M, C \vdash \neg e_1 : \text{Int}} \quad \text{[Neg]}
\]

\[
O, M, C \vdash e_1 : \text{Int} \\
O, M, C \vdash e_2 : \text{Int} \\
op \in \{*, +, -, /\} \\
\overline{O, M, C \vdash e_1 \, \text{op} \, e_2 : \text{Int}} \quad \text{[Arith]}
\]

The wrinkle in the rule for equality is that any types may be freely
compared except \text{Int}, \text{String} and \text{Bool}, which may only be compared with
objects of the same type.

\[
O, M, C \vdash e_1 : T_1 \\
O, M, C \vdash e_2 : T_2 \\
T_1 \in \{\text{Int, String, Bool}\} \lor T_2 \in \{\text{Int, String, Bool}\} \Rightarrow T_1 = T_2 \\
\overline{O, M, C \vdash e_1 = e_2 : \text{Bool}} \quad \text{[Equal]}
\]

The final cases are type checking rules for attributes and methods. For
a class \(C\), let the object environment \(O_C\) give the types of all attributes of
\(C\) (including any inherited attributes). More formally, if \(x\) is an attribute
(inherited or not) of \(C\), and the declaration of \(x\) is \(x : T\), then

\[O_C(x) = \begin{cases} 
\text{SELF\_TYPE}_C & \text{if } T = \text{SELF\_TYPE} \\
T & \text{otherwise} 
\end{cases} \]

The method environment \(M\) is global to the entire program and defines
for every class \(C\) the signatures of all of the methods of \(C\) (including any
inherited methods).

The two rules for type checking attribute definitions are similar the
rules for \text{let}. The essential difference is that attributes are visible within
their initialization expressions. Note that self is bound in the initialization.

\[
\begin{align*}
O_C(x) &= T_0 \\
O_C[\text{SELF\_TYPE}_C/self], M, C &\vdash e_1 : T_1 \\
T_1 &\leq T_0 \\
O_C, M, C &\vdash x : T_0 \leftarrow e_1; \\
\end{align*}
\]

[Attr-Init]

\[
\begin{align*}
O_C(x) &= T \\
O_C, M, C &\vdash x : T; \\
\end{align*}
\]

[Attr-No-Init]

The rule for typing methods checks the body of the method in an environment where \( O_C \) is extended with bindings for the formal parameters and self. The type of the method body must conform to the declared return type.

\[
\begin{align*}
M(C, f) &= (T_1, \ldots, T_n, T_0) \\
O_C[\text{SELF\_TYPE}_C/self][T_1/x_1] \ldots [T_n/x_n], M, C &\vdash e : T'_0 \\
T'_0 &\leq \begin{cases} 
\text{SELF\_TYPE}_C & \text{if } T_0 = \text{SELF\_TYPE} \\
T_0 & \text{otherwise} 
\end{cases} \\
O_C, M, C &\vdash f(x_1 : T_1, \ldots, x_n : T_n) : T_0 \{ e \}; \\
\end{align*}
\]

[Method]

12 Operational Semantics

This section contains a mostly formal presentation of the operational semantics for the Cool language. The operational semantics define for every Cool expression what value it should produce in a given context. The context has three components: an environment, a store, and a self object. These components are described in the next section. Section 12.2 defines the syntax used to refer to Cool objects, and Section 12.3 defines the syntax used to refer to class definitions.

Keep in mind that a formal semantics is a specification only—it does not describe an implementation. The purpose of presenting the formal semantics is to make clear all the details of the behavior of Cool expressions. How this behavior is implemented is another matter.

12.1 Environment and the Store

Before we can present a semantics for Cool we need a number of concepts and a considerable amount of notation. An environment is a mapping of variable identifiers to locations. Intuitively, an environment tells us for a
given identifier the address of the memory location where that identifier’s value is stored. For a given expression, the environment must assign a location to all identifiers to which the expression may refer. For the expression, e.g., \(a + b\), we need an environment that maps \(a\) to some location and \(b\) to some location. We’ll use the following syntax to describe environments, which is very similar to the syntax of type assumptions used in Section 11.

\[ E = [a : l_1, b : l_2] \]

This environment maps \(a\) to location \(l_1\), and \(b\) to location \(l_2\).

The second component of the context for the evaluation of an expression is the store (memory). The store maps locations to values, where values in Cool are just objects. Intuitively, a store tells us what value is stored in a given memory location. For the moment, assume all values are integers. A store is similar to an environment:

\[ S = [l_1 \rightarrow 55, l_2 \rightarrow 77] \]

This store maps location \(l_1\) to value 55 and location \(l_2\) to value 77.

Given an environment and a store, the value of an identifier can be found by first looking up the location that the identifier maps to in the environment and then looking up the location in the store.

\[
\begin{align*}
    E(a) &= l_1 \\
    S(l_1) &= 55
\end{align*}
\]

Together, the environment and the store define the execution state at a particular step of the evaluation of a Cool expression. The double indirection from identifiers to locations to values allows us to model variables. Consider what happens if the value 99 is assigned variable \(a\) in the environment and store defined above. Assigning to a variable means changing the value to which it refers but not its location. To perform the assignment, we look up the location for \(a\) in the environment \(E\) and then change the mapping for the obtained location to the new value, giving a new store \(S'\).

\[
\begin{align*}
    E(a) &= l_1 \\
    S' &= S[99/l_1]
\end{align*}
\]

The syntax \(S[v/l]\) denotes a new store that is identical to the store \(S\), except that \(S'\) maps location \(l\) to value \(v\). For all locations \(l'\) where \(l' \neq l\), we still have \(S'(l') = S(l')\).

The store models the contents of memory of the computer during program execution. Assigning to a variable modifies the store.
There are also situations in which the environment is modified. Consider the following Cool fragment:

```cool
define c : Int := 33 in
c
```

When evaluating this expression, we must introduce the new identifier `c` into the environment before evaluating the body of the `let`. If the current environment and state are $E$ and $S$, then we create a new environment $E'$ and a new store $S'$ defined by:

$$
l_c = \text{newloc}(S)
$$
$$
E' = E[l_c/c]
$$
$$
S' = S[33/l_c]
$$

The first step is to allocate a location for the variable $c$. The location should be fresh, meaning that the current store does not have a mapping for it. The function `newloc()` applied to a store gives us an unused location in that store. We then create a new environment $E'$, which maps $c$ to $l_c$ but also contains all of the mappings of $E$ for identifiers other than $c$. Note that if $c$ already has a mapping in $E$, the new environment $E'$ hides this old mapping. We must also update the store to map the new location to a value. In this case $l_c$ maps to the value 33, which is the initial value for $c$ as defined by the `let`-expression.

The example in this subsection oversimplifies Cool environments and stores a bit, because simple integers are not Cool values. Even integers are full-fledged objects in Cool.

### 12.2 Syntax for Cool Objects

Every Cool value is an object. Objects contain a list of named attributes, a bit like records in C. In addition, each object belongs to a class. We use the following syntax for values in Cool:

$$
v = X(a_1 = l_1, a_2 = l_2, \ldots, a_n = l_n)
$$

Read the syntax as follows: The value $v$ is a member of class $X$ containing the attributes $a_1, \ldots, a_n$ whose locations are $l_1, \ldots, l_n$. Note that the attributes have an associated location. Intuitively this means that there is some space in memory reserved for each attribute.

For base objects of Cool (i.e., `Ints`, `Strings`, and `Bools`) we use a special case of the above syntax. Base objects have a class name, but their attributes
are not like attributes of normal classes, because they cannot be modified. Therefore, we describe base objects using the following syntax:

\[\begin{align*}
\text{Int}(5) \\
\text{Bool}(true) \\
\text{String}(4, \text{"Cool"})
\end{align*}\]

For Ints and Bools, the meaning is obvious. Strings contain two parts, the length and the actual sequence of ASCII characters.

### 12.3 Class definitions

In the rules presented in the next section, we need a way to refer to the definitions of attributes and methods for classes. Suppose we have the following Cool class definition:

```plaintext
class B {
    s : String := "Hello";
    g (y:String) : Int {
        y.concat(s)
    };
    f (x:Int) : Int {
        x+1
    };
};

class A inherits B {
    a : Int;
    b : B := new B;
    f(x:Int) : Int {
        x+a
    };
};
```

Two mappings, called `class` and `implementation`, are associated with class definitions. The `class` mapping is used to get the attributes, as well as their types and initializations, of a particular class:

\[
\text{class}(A) = (s : \text{String} \leftarrow \text{"Hello"}, \ a : \text{Int} \leftarrow 0, \ b : B \leftarrow \text{new B})
\]

Note that the information for class \(A\) contains everything that it inherited from class \(B\), as well as its own definitions. If \(B\) had inherited other attributes, those attributes would also appear in the information for \(A\). The
attributes are listed in the order they are inherited and then in source order: all the attributes from the greatest ancestor are listed first in the order in which they textually appear, then the attributes of the next greatest ancestor, and so on, on down to the attributes defined in the particular class. We rely on this order in describing how new objects are initialized.

The general form of a class mapping is:

\[
\text{class}(X) = (a_1 : T_1 \leftarrow e_1, \ldots, a_n : T_n \leftarrow e_n)
\]

Note that every attribute has an initializing expression, even if the Cool program does not specify one for each attribute. The default initialization for a variable or attribute is the default of its type. The default of Int is 0, the default of String is "," , the default of Bool is false , and the default of any other type is void .

The implementation mapping gives information about the methods of a class. For the above example, implementation of A is defined as follows:

\[
\begin{align*}
\text{implementation}(A, f) & = (x, x + a) \\
\text{implementation}(A, g) & = (y, y.concat(s))
\end{align*}
\]

In general, for a class \(X\) and a method \(m\),

\[
\text{implementation}(X, m) = (x_1, x_2, \ldots, x_n, e_{body})
\]

specifies that method \(m\) when invoked from class \(X\), has formal parameters \(x_1, \ldots, x_n\), and the body of the method is expression \(e_{body}\).

### 12.4 Operational Rules

Equipped with environments, stores, objects, and class definitions, we can now attack the operational semantics for Cool. The operational semantics is described by rules similar to the rules used in type checking. The general form of the rules is:

\[
\vdots
\]

\[so, S, E \vdash e_1 : v, S'
\]

The rule should be read as: In the context where self is the object so , the store is S , and the environment is E , the expression \(e_1\) evaluates to object \(v\) and the new store is \(S'\). The dots above the horizontal bar stand for other statements about the evaluation of sub-expressions of \(e_1\).

\[\footnotesize^5\text{A tiny point: We are allowing void to be used as an expression here. There is no expression for void available to Cool programmers.}\]
Besides an environment and a store, the evaluation context contains a self object so. The self object is just the object to which the identifier self refers if self appears in the expression. We do not place self in the environment and store because self is not a variable—it cannot be assigned to. Note that the rules specify a new store after the evaluation of an expression. The new store contains all changes to memory resulting as side effects of evaluating expression e₁.

The rest of this section presents and briefly discusses each of the operational rules. A few cases are not covered; these are discussed at the end of the section.

\[
\begin{align*}
& so, S_1, E ⊢ e_1 : v_1, S_2 \\
& E(Id) = l_1 \\
& S_3 = S_2[v_1/l_1] \\
& so, S_1, E ⊢ Id ← e_1 : v_1, S_3 \\
& \quad \text{[Assign]}
\end{align*}
\]

An assignment first evaluates the expression on the right-hand side, yielding a value \(v_1\). This value is stored in memory at the address for the identifier.

The rules for identifier references, self, and constants are straightforward:

\[
\begin{align*}
& so, S, E ⊢ Id : v, S \\
& \quad \text{[Var]}
\end{align*}
\]

\[
\begin{align*}
& so, S, E ⊢ self : so, S \\
& \quad \text{[Self]}
\end{align*}
\]

\[
\begin{align*}
& so, S, E ⊢ true : \text{Bool}(true), S \\
& \quad \text{[True]}
\end{align*}
\]

\[
\begin{align*}
& so, S, E ⊢ false : \text{Bool}(false), S \\
& \quad \text{[False]}
\end{align*}
\]

\[
\begin{align*}
& so, S, E ⊢ i : \text{Int}(i), S \\
& \quad \text{[Int]}
\end{align*}
\]

\[
\begin{align*}
& so, S, E ⊢ s : \text{String}(l, s), S \\
& \quad \text{[String]}
\end{align*}
\]
A new expression is more complicated than one might expect:

\[
T_0 = \begin{cases} 
X & \text{if } T = \text{SELF\_TYPE} \text{ and } \text{so} = X(\ldots) \\
T & \text{otherwise}
\end{cases}
\]

\[
\begin{align*}
\text{class}(T_0) &= (a_1 : T_1 \leftarrow e_1, \ldots, a_n : T_n \leftarrow e_n) \\
l_i &= \text{newloc}(S_1), \text{ for } i = 1 \ldots n \text{ and each } l_i \text{ is distinct} \\
v_1 &= T_0(a_1 = l_1, \ldots, a_n = l_n) \\
S_2 &= S_1[D_{T_1}/l_1, \ldots, D_{T_n}/l_n] \\
v_1, S_2, [a_1 : l_1, \ldots, a_n : l_n] &\vdash \{a_1 \leftarrow e_1; \ldots; a_n \leftarrow e_n;\} : v_2, S_3 \\
\text{so, } S_1, E &\vdash \text{new } T : v_1, S_3 \quad [\text{New}]
\end{align*}
\]

The tricky thing in a new expression is to initialize the attributes in the right order. Note also that, during initialization, attributes are bound to the default of the appropriate class.

\[
\begin{align*}
\text{so, } S_1, E &\vdash e_1 : v_1, S_2 \\
\text{so, } S_2, E &\vdash e_2 : v_2, S_3 \\
&\vdots \\
\text{so, } S_n, E &\vdash e_n : v_n, S_{n+1} \\
\text{so, } S_{n+1}, E &\vdash e_0 : v_0, S_{n+2} \\
v_0 &= X(a_1 = l_{a_1}, \ldots, a_m = l_{a_m}) \\
\text{implementation}(X, f) &= (x_1, \ldots, x_n, e_{n+1}) \\
l_{x_i} &= \text{newloc}(S_{n+2}), \text{ for } i = 1 \ldots n \text{ and each } l_{x_i} \text{ is distinct} \\
S_{n+3} &= S_{n+2}[v_1/l_{x_1}, \ldots, v_n/l_{x_n}] \\
v_0, S_{n+3}, [a_1 : l_{a_1}, \ldots, a_m : l_{a_m}, x_1 : l_{x_1}, \ldots, x_n : l_{x_n}] &\vdash e_{n+1} : v_{n+1}, S_{n+4} \\
\text{so, } S_1, E &\vdash e_0.f(e_1, \ldots, e_n) : v_{n+1}, S_{n+4} \quad [\text{Dispatch}]
\end{align*}
\]

\[
\begin{align*}
\text{so, } S_1, E &\vdash e_1 : v_1, S_2 \\
\text{so, } S_2, E &\vdash e_2 : v_2, S_3 \\
&\vdots \\
\text{so, } S_n, E &\vdash e_n : v_n, S_{n+1} \\
\text{so, } S_{n+1}, E &\vdash e_0 : v_0, S_{n+2} \\
v_0 &= X(a_1 = l_{a_1}, \ldots, a_m = l_{a_m}) \\
\text{implementation}(T, f) &= (x_1, \ldots, x_n, e_{n+1}) \\
l_{x_i} &= \text{newloc}(S_{n+2}), \text{ for } i = 1 \ldots n \text{ and each } l_{x_i} \text{ is distinct} \\
S_{n+3} &= S_{n+2}[v_1/l_{x_1}, \ldots, v_n/l_{x_n}] \\
v_0, S_{n+3}, [a_1 : l_{a_1}, \ldots, a_m : l_{a_m}, x_1 : l_{x_1}, \ldots, x_n : l_{x_n}] &\vdash e_{n+1} : v_{n+1}, S_{n+4} \\
\text{so, } S_1, E &\vdash e_0@T.f(e_1, \ldots, e_n) : v_{n+1}, S_{n+4} \quad [\text{StaticDispatch}]
\end{align*}
\]
The two dispatch rules do what one would expect. The arguments are evaluated and saved. Next, the expression on the left-hand side of the “.” is evaluated. In a normal dispatch, the class of this expression is used to determine the method to invoke; otherwise the class is specified in the dispatch itself.

\[
\begin{align*}
so, S_1, E \vdash e_1 : \text{Bool}(true), S_2 \\
so, S_2, E \vdash e_2 : v_2, S_3 \\
\quad \therefore so, S_1, E \vdash \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \text{ fi : } v_2, S_3 \quad \text{[If-True]} \\
so, S_1, E \vdash e_1 : \text{Bool}(false), S_2 \\
so, S_2, E \vdash e_3 : v_3, S_3 \\
\quad \therefore so, S_1, E \vdash \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \text{ fi : } v_3, S_3 \quad \text{[If-False]}
\end{align*}
\]

There are no surprises in the if-then-else rules. Note that value of the predicate is a \texttt{Bool} object, not a boolean.

\[
\begin{align*}
so, S_1, E \vdash e_1 : v_1, S_2 \\
so, S_2, E \vdash e_2 : v_2, S_3 \\
\vdots \\
so, S_n, E \vdash e_n : v_n, S_{n+1} \\
\quad \therefore so, S_1, E \vdash \{ \, e_1; e_2; \ldots ; e_n ; \, \} : v_n, S_{n+1} \quad \text{[Sequence]}
\end{align*}
\]

Blocks are evaluated from the first expression to the last expression, in order. The result is the result of the last expression.

\[
\begin{align*}
so, S_1, E \vdash e_1 : v_1, S_2 \\
l_1 = \text{newloc}(S_2) \\
S_3 = S_2[l_1/l_1] \\
E' = E[l_1/Id] \\
so, S_3, E' \vdash e_2 : v_2, S_4 \\
\quad \therefore so, S_1, E \vdash \text{let } Id : T_1 \leftarrow e_1 \text{ in } e_2 : v_2, S_4 \quad \text{[Let]}
\end{align*}
\]

A \texttt{let} evaluates any initialization code, assigns the result to the variable at a fresh location, and evaluates the body of the \texttt{let}. (If there is no initialization, the variable is initialized to the default value of \(T_1\).) We give the operational semantics only for the case of \texttt{let} with a single variable. The semantics of a multiple \texttt{let}

\[
\text{let } x_1 : T_1 \leftarrow e_1, \ x_2 : T_2 \leftarrow e_2, \ldots, \ x_n : T_n \leftarrow e_n \text{ in } e
\]
is defined to be the same as

\[
\text{let } x_1 : T_1 \leftarrow e_1 \text{ in } (\text{let } x_2 : T_2 \leftarrow e_2, \ldots, \ x_n : T_n \leftarrow e_n \text{ in } e)
\]
so, $S_1, E \vdash e_0 : v_0, S_2$

$v_0 = X(\ldots)$

$T_i = $ closest ancestor of $X$ in $\{T_1, \ldots, T_n\}$

$l_0 = \text{newloc}(S_2)$

$S_3 = S_2[v_0/l_0]$

$E' = E[l_0/Id_i]$

so, $S_3, E' \vdash e_i : v_1, S_4$

Note that the case rule requires that the class hierarchy be available in some form at runtime, so that the correct branch of the case can be selected. This rule is otherwise straightforward.

so, $S_1, E \vdash e_1 : \text{Bool}(\text{true}), S_2$

so, $S_2, E \vdash e_2 : v_2, S_3$

so, $S_3, E \vdash \text{while } e_1 \text{ loop } e_2 \text{ pool } : \text{void}, S_4$

so, $S_1, E \vdash \text{while } e_1 \text{ loop } e_2 \text{ pool } : \text{void}, S_4$

[Case]

There are two rules for while: one for the case where the predicate is true and one for the case where the predicate is false. Both cases are straightforward. The two rules for isvoid are also straightforward:

so, $S_1, E \vdash e_1 : \text{void}, S_2$

so, $S_1, E \vdash \text{isvoid } e_1 : \text{Bool}(\text{true}), S_2$

[IsVoid-True]

so, $S_1, E \vdash e_1 : X(\ldots), S_2$

so, $S_1, E \vdash \text{isvoid } e_1 : \text{Bool}(\text{false}), S_2$

[IsVoid-False]

The remainder of the rules are for the primitive arithmetic, logical, and comparison operations except equality. These are all easy rules.

so, $S_1, E \vdash e_1 : \text{Bool}(b), S_2$

$v_1 = \text{Bool}(\neg b)$

so, $S_1, E \vdash \text{not } e_1 : v_1, S_2$

[Not]
so, $S_1, E \vdash e_1 : \text{Int}(i_1), S_2$

so, $S_2, E \vdash e_2 : \text{Int}(i_2), S_3$

$op \in \{\leq, <\}$

\[
v_1 = \begin{cases} 
\text{Bool}(true), & \text{if } i_1 \ op \ i_2 \\
\text{Bool}(false), & \text{otherwise}
\end{cases}
\]

so, $S_1, E \vdash e_1 \ op \ e_2 : v_1, S_3$  \[\text{[Comp]}\]

so, $S_1, E \vdash e_1 : \text{Int}(i_1), S_2$

\[
v_1 = \text{Int}(-i_1)
\]

so, $S_1, E \vdash \neg e_1 : v_1, S_2$  \[\text{[Neg]}\]

so, $S_1, E \vdash e_1 : \text{Int}(i_1), S_2$

so, $S_2, E \vdash e_2 : \text{Int}(i_2), S_3$

$op \in \{\ast, +, -, /\}$

\[
v_1 = \text{Int}(i_1 \ op \ i_2)
\]

so, $S_1, E \vdash e_1 \ op \ e_2 : v_1, S_3$  \[\text{[Arith]}\]

Cool Ints are 32-bit two’s complement signed integers; the arithmetic operations are defined accordingly.

The notation and rules given above are not powerful enough to describe how objects are tested for equality, or how runtime exceptions are handled. For these cases we resort to an English description.

In $e_1 = e_2$, first $e_1$ is evaluated and then $e_2$ is evaluated. The two objects are compared for equality by first comparing their pointers (addresses). If they are the same, the objects are equal. The value void is not equal to any object except itself. If the two objects are of type String, Bool, or Int, their respective contents are compared.

In addition, the operational rules do not specify what happens in the event of a runtime error. Execution aborts when a runtime error occurs. The following list specifies all possible runtime errors.

1. A dispatch (static or dynamic) on void.

2. A case on void.

3. Execution of a case statement without a matching branch.

4. Division by zero.

5. Substring out of range.

6. Heap overflow.
Finally, the rules given above do not explain the execution behaviour for dispatches to primitive methods defined in the Object, IO, or String classes. Descriptions of these primitive methods are given in Sections 7.3–7.5.

13 Cool vs. Java and other OO languages

It may be useful to summarize some similarities and differences between Cool and other OO languages with which you may be familiar. I will also propose a few ways in which you might extend the language, if you want an extra challenge.

13.1 Classes and Features

A class in Cool is much like a class in Java or C++, and “inherits” is like “extends” in those languages. Note that Cool does not have interfaces or the “implements” relation like Java, nor multiple inheritance like C++. This is a significant simplification for implementing object-oriented method dispatch, because we need only one dispatch table (vtable) for each class.

Features are what C++ programmers might call “members”. You might call an attribute a “field” or a “data member”. In Java terms, all fields in Cool are private and all methods are public. The common convention of starting a class name with a capital letter and a field or method name with a lower case letter is a lexical rule in Cool. Cool does not allow overloading of field or method names, but it does allow a method and a field to have the same name.

In Java, every class defines a type, but not every type is a class. The “primitive” types int, boolean, float, etc. are not classes, although there are classes like Integer that “wrap” the primitive types. In Cool, the built-in types like “Int” and “Bool” are also classes. However, the built-in classes come with a host of restrictions and special rules. You can’t inherit from (subclass) or redefine Int, String, or Bool, and they are initialized to appropriate default values rather than void. While the operational semantics is not as clear as one would like, it also appears that Int, Bool, and String have value semantics rather than reference semantics; setting \( x := y \) gives \( x \) a copy of the value in \( y \), rather than making \( x \) and \( y \) share an object reference, if \( x \) and \( y \) are of type Int, Bool, or String. Apparently the point of all these special rules is so that we can treat the basic classes Bool and Int (and maybe String too) like the corresponding primitives in Java.

Although the syntax of variable (attribute) definitions is slightly different in Cool, there is no essential difference between
x: Int := 5;

in Cool and

int x = 5;

in Java.

self in Cool is essentially this in Java. There is no "self type" in Java, and while it is convenient, there are good semantic arguments for not providing something like SELF_TYPE.

Consider:

```java
class Coord {
    x: Integer;
    y: Integer;
    init(xval: Integer, yval: Integer): Coord {
        x := xval; y := yval;
    }

    copy() : SELF_TYPE { (new Coord).init(x,y); }
};

class Coord3d inherits Coord {
    z: Integer;
    init(xval: Integer, yval: Integer, zval: Integer) {
        x := xval; y := yval; z := zval;
    }
};
```

Note that Coord3d has an inherited method copy( ) that returns an object of type Coord3d, but the inherited method fails to copy the value of the z attribute, which is probably a mistake.

13.2 Type checking

The distinction between the static type of an attribute and the dynamic type of the object to which it refers is essentially identical to the distinction between variable type and object type in Java, and the type soundness rules are essentially equivalent. Java’s rules are much more complex when you add in primitive (non-object) types, arrays, and generics.
13.3 Attributes

Initialization rules are similar to Java, but Java also performs a flow-sensitive analysis to ensure that a variable is initialized before its first use in a method. That would be an excellent extension to consider for Cool, if you have time after the type checking.

13.4 Void

The “void” value of Cool is not really related to the “void” type in Java. It is much closer to “null”, which like “void” is a value that belongs to all object types. There is a small difference in the treatment of the basic classes. In Java, int and boolean are not classes at all; primitive types are something different. In Cool, Int and Boolean are classes, but their default values are 0 and false respectively; they can never be void. String is a class in Java but in Cool it is one of the special basic classes, with a default value “” (the empty string) rather than void (null pointer). Note that null is a constant in Java, but there is no constant “void” in Cool.

13.5 Methods

Because Cool does not allow overloading (there can’t be both a foo(Int, Int) and a foo(Bool) in the same method), it requires stricter rules for overriding (if foo(Int, Int) is inherited from the superclass, the subclass can’t define a method foo(Bool)).

13.6 Expressions

Cool is an “expression-oriented” language, which means that (among other things) a block of statements is treated as an expression that returns the last value computed. In general, some constructs that don’t have values in Java, do have values in Cool.

13.6.1 Dispatch

The rules for (expr).foo() and foo() (which is shorthand for self.foo()) are essentially as in Java. There is no Java equivalent to the e@T.foo() form of dispatch, but one of the ways @ is used is similar to the way super is used in Java. @ in Cool permits referring to a hidden method from anywhere, while Java’s super is more restrictive. If you agree that SELF_TYPE is dangerous, you might also consider @ dangerous.
13.6.2 Conditionals

Note that since Cool is an expression-oriented language, the “else” branch is *not* optional: The conditional expression must produce a value when the predicate is false as well as when it is true. In this regard it is like the C and Java ternary expression `p?t:e` and not like an `if` statement. Like Java (and unlike C and C++), the predicate expression must be `Bool`.

13.6.3 Loops

Technically loops also have values, but a loop that executes zero times returns the special value `void`.

13.6.4 Blocks

Nothing special.

13.6.5 Let

Although syntactically the `let` expression looks like it belongs in ML, the only real difference from a Java `{...}` block with some local variable declarations is in the rules for later declarations shadowing earlier declarations, as in `let x: Int := 2, x: Int := x+5 in x + y`.

The vague statement about `<expr>` extending “as far as possible” is a hint for resolving an ambiguity in the grammar.

13.6.6 Case

The “case” statement in Cool looks like a Java switch statement, but it’s quite different. It’s more like a series of “if” tests using “instanceOf”, but its main use is like a Java cast. Where a Java programmer would write

```java
Foo f = (Foo) o.m(x);
```

a Cool programmer can write

```cool
f: Foo := case o.m(x) of y: Foo => y;
```

13.6.7 Isvoid

`void` in Cool is similar to `null` in Java, especially in that every type has a `void` value. The existence of a special value shared by many types is a convenience for programming but an extra complication in type checking.
13.6.8 Arithmetic and Comparisons

Arithmetic is simple because the only numeric type is Int.

Note the special rule on comparisons with Int, Bool, an String. A good language extension would be to provide a warning whenever the two objects being compared are not either of the same static type or in an ancestor relation.

Note that the “comparison operations” section of the first part of the manual does not specify whether Cool’s = has the meaning of Java’s .equals or of Java’s ==. The formal semantics also doesn’t specify. Finally, an informal English description indicates that the meaning of = is like Java’s == for most classes. It is like .equals for the basic classes Bool and Int, which is really like comparison of primitive types in Java. Comparison of Strings is like .equals also, which is different from == in Java (two identical strings in Java may not be ==).

14 Acknowledgements

Cool is based on Sather164, which is itself based on the language Sather. Portions of this document were cribbed from the Sather164 manual; in turn, portions of the Sather164 manual are based on Sather documentation written by Stephen M. Omohundro.

A number people have contributed to the design and implementation of Cool, including Manuel Fähndrich, David Gay, Douglas Hauge, Megan Jacoby, Tendo Kayiira, Carleton Miyamoto, and Michael Stoddart. Joe Darcy updated Cool to the current version.

Flaws in the current version are most likely the fault of Michal Young, who made several small revisions for his class at University of Oregon. Let him know about his blunders: michal@cs.uoregon.edu
